

# Data Analysis of LLRF Measurements at FLASH

Shilun Pei and Chris Adolphsen

Nov. 16 – Nov. 20, 2008

# Motivation and Introduction

---

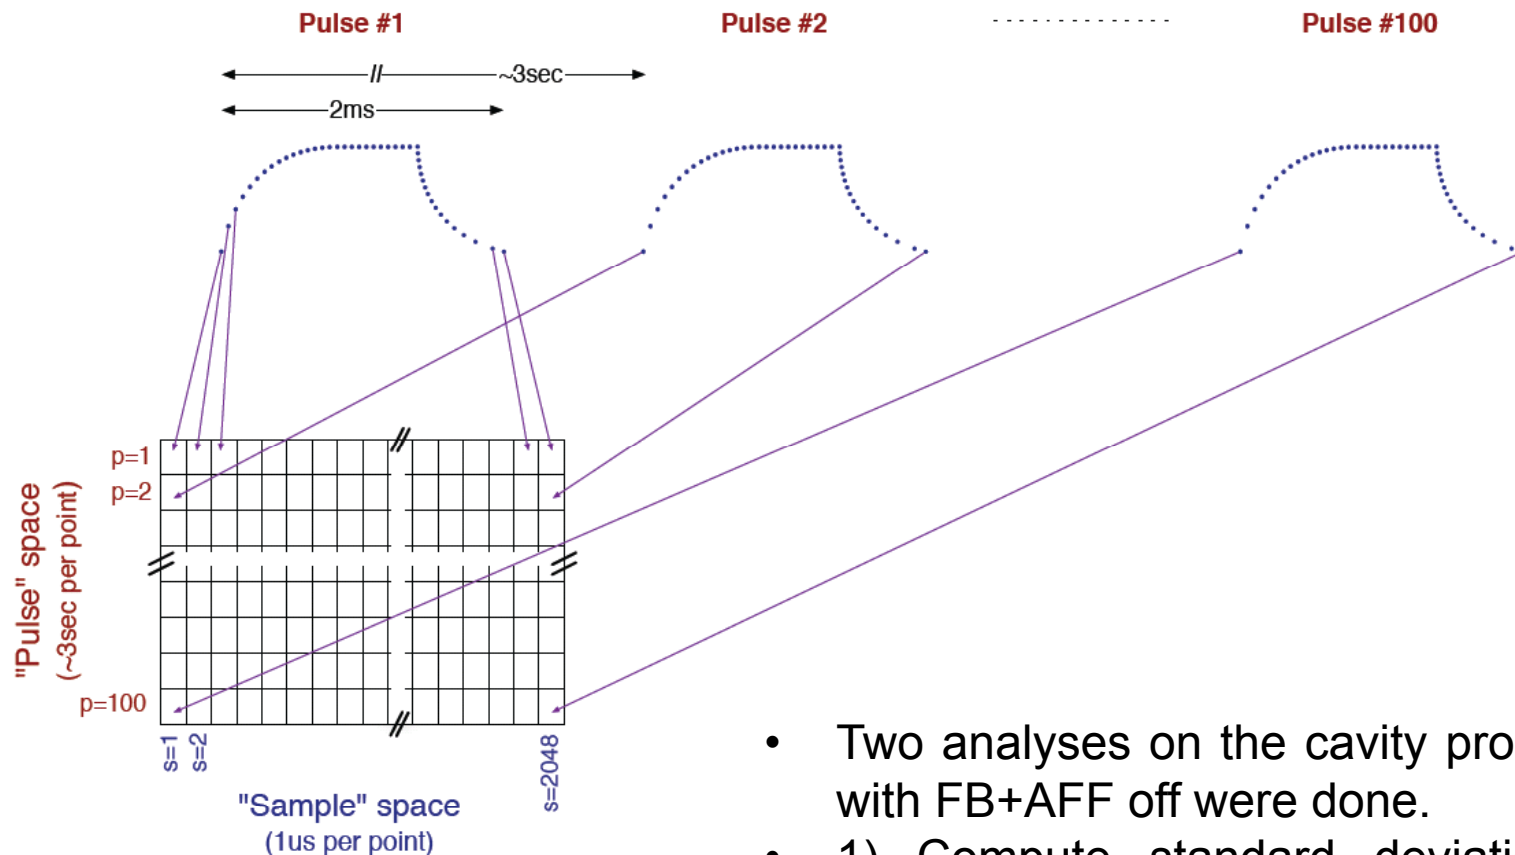

- Motivation: analyze FLASH LLRF real time data (they have an impressive DAQ system), measure the system stability, determine the electronic noise levels, gauge the perturbations to the system, etc.
- Data was collected on Sep 17, 08 for the following 3 setups:
  - No beam, FB off, AFF off.
  - No beam, FB on, AFF off.
  - No beam, FB on, AFF on.
- For each set of measurements, the phase and amplitude waveforms (both from the cavity input and pickup couplers) of all cavities in the three cryomodules (ACC4-ACC6) were recorded simultaneously for 100 pulses (one every 3 sec).
- Data and analyzing scripts can be found at <http://public.me.com/carwardine>.

# Time Domain Analysis

---

- Calibrated the input forward signal at first flattop in MV/m (assuming the cavity probe signal is calibrated correctly).
- Averaged sets of 4 points to eliminate the 250 kHz LLRF signal leakage effect.
- Computed the standard deviation at each time step for the 100 pulses in each set of measurements.
- The standard deviation before the RF turns on is a measure of electronic noise, while the standard deviation when the RF is on includes the rf jitter. To compute the jitter, the noise contribution was subtracted in quadrature.
- This method was used to analyze the vector sum, input forward and cavity probe signals.

# Frequency Domain Analysis

This method was only used for probe signal analysis.

- Two analyses on the cavity probe flat top data with FB+AFF off were done.
- 1) Compute standard deviation of 'Pulses' versus 'Sample' time.
- 2) Compute FFT of the 'Pulses' at two fixed sample times (beginning and end of the flattop).

# Outline of Key Findings

---

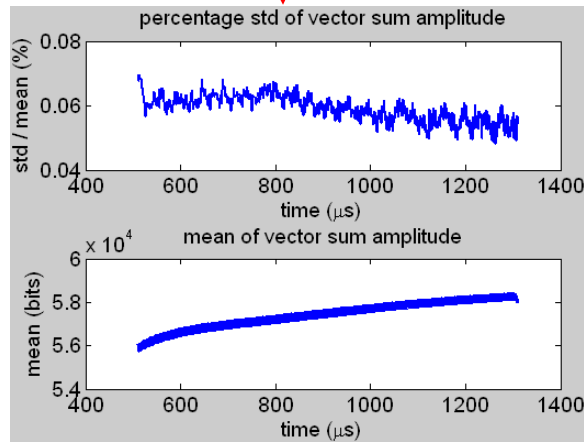

- The FB + AFF controls work well to flatten the vector sum amplitude and phase.
- Input RF very stable ( $\sim 0.1\%$  level) with FB and AFF off.
- Jitter on cavity probe signals dominated by variations in pulse-to-pulse cavity detuning profile.
  - Jitter essentially random pulse to pulse with large cavity to cavity variations (probably uncorrelated).
  - Jitter does not scale simply with  $\text{gradient}^2$  (in 14-24 MV/m range) – suggests large variations in mechanical stiffness (factor 2 difference).

# Vector Sum Amplitude

FB Off / AFF Off / No Beam

FB On / AFF Off / No Beam

FB On / AFF On / No Beam

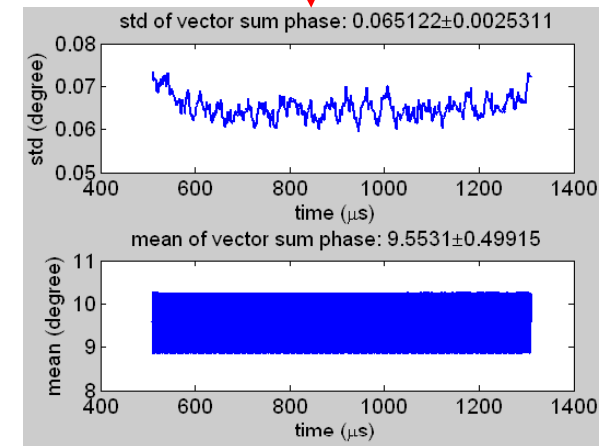

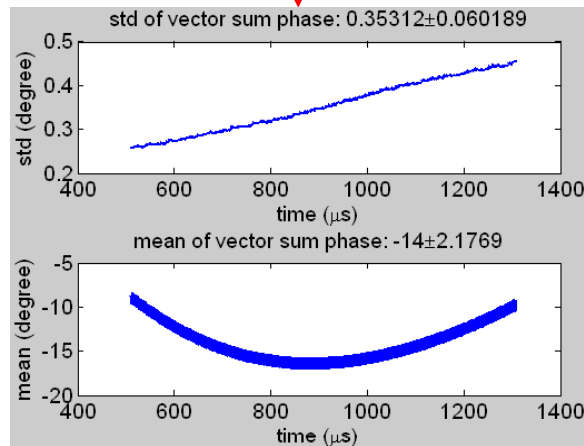

Flat top amplitude percentage standard deviation is decreased by factor 2-6.  
FB can decrease the percentage std, AFF can flat the flat top amplitude.

# Vector Sum Phase

FB Off / AFF Off / No Beam

FB On / AFF Off / No Beam

FB On / AFF On / No Beam

The phase standard deviation is decreased by factor 3-7.  
FB can decrease the phase std, AFF can flat the flat top phase.

# For. and Refl. Signals

---

- Input signals not calibrated (i.e., amplitude not proportional to gradient), noisy (electronic) and some contain 250 kHz leakage.
- Significant reflected-to-forward signal coupling (i.e., signals not all the same shape – could not de-convolute them perfectly).
- Reflected signals indicate significant initial detuning (i.e. reflected amplitude is not zero near end of first flattop) – expect  $\sim 300$  Hz LFD over 1 ms at these gradients.
- FB+AFF off amplitude very stable pulse to pulse:  $\sim 0.07\%$  RMS in first flattop and  $0.15\%$  RMS in second, which may be larger due to ref-fwd coupling or if jitter dominated by noise on common RF drive (i.e. independent on RF amplitude).
- FB On, AFF Off: input signal shape change as expected for detuning (i.e. no piezo compensation).
- FB On, AFF On: Adds strange shape to first flattop and increase jitter.

# Cavity Probe Signals

---

- See smooth pulse-to-pulse variations in probe signal shape that grow along the pulse, suggesting jitter is an integrated effect and not dominated by fast changes in  $Q$  (as in dark current and multipacting).
- Jitter is a few tenths of percent at beginning of flattop and grows up to 4% by end of flattop.
- Higher gradient cavities have higher jitter in general, but it does not scale simply with  $\text{gradient}^2$ .
- Jitter at flattop end correlates well with detuning variation just after RF shut-off, suggesting that variations in pulse-to-pulse detuning is driving the probe signal jitter.
- Jitter essentially random pulse to pulse with large cavity to cavity variations (uncorrelated between cavities).
  - See some peaks in FFT spectrum but they do not contribute significantly to jitter.

FB Off / AFF Off / No Beam

FB On / AFF Off / No Beam

FB On / AFF On / No Beam

Only 1<sup>st</sup> flat top fractional jitter is shown below! Noise effect is eliminated roughly!

The fractional jitter on the 1<sup>st</sup> input flat top rf amplitude is about 0.05-0.2% with FB and AFF off.

The cause of the large fractional jitter and the strange transient bump on the 1<sup>st</sup> input RF flat top with FB+AFF on might be that the AFF is turned on part way up the fill (Brain Chase, FNAL). Suggestions are to ramp up AFF gain in a linear way to reach full gain at flattop. Further development on AFF is still needed.

FB Off / AFF Off / No Beam

FB On / AFF Off / No Beam

FB On / AFF On / No Beam

**Only 2<sup>nd</sup> flat top fractional jitter is shown below! Noise effect is eliminated roughly!**

The fractional jitter on the 2<sup>nd</sup> input flat top RF amplitude is about 0.07-0.47% with FB and AFF off. It seems both FB and AFF will introduce a large fractional jitter for the 2<sup>nd</sup> input RF flat top amplitude.

The fractional jitter for the 2<sup>nd</sup> input flat top with FB+AFF off is about factor 2 of that for the 1<sup>st</sup> flat top (the RF amplitude for the 2<sup>nd</sup> flat top is roughly half of that for the 1<sup>st</sup> flat top). It seems the jitter is dominated by some effect not related with the RF amplitude, which might come from the electronic noise.

FB+AFF can reduce the cavity probe fractional jitter and flatten the cavity flat top to some extent.

Dark current effect may exist (after further study, this possibility was eliminated) or some cavities are very sensitive to the Lorentz detuning variation effect (confirmed by further study).

- The cavity input rf amplitude jitter (FB off, AFF off) appears to be very small (0.05%-0.2%) for the 1<sup>st</sup> flat top. Even with noise effect, the jitter is still smaller than 0.6%.
- The FB + AFF controls work well to flatten the vector sum amplitude and phase, although AFF adds strange bumps to the rf waveform at the 1<sup>st</sup> flat top and is the main cause of rf jitter – the AFF might be turned on part way up the fill (Brain Chase, FNAL). Suggestions are to ramp up AFF gain in a linear way to reach full gain at flattop. Further development on AFF is still needed.
- The fractional jitter for the 2<sup>nd</sup> input flat top is about factor 2 of that for the 1<sup>st</sup> flat top (which they should be same theoretically). Since the RF amplitude for the 2nd flat top is roughly half of that for the 1st flat top, it seems the jitter is dominated by some effect not related with the RF amplitude, which might come from the electronic noise.
- The cavity probe signals are particularly interesting as their jitter is much larger (up to 4% with noise) than that of the input rf, and grows along the pulse. Either some of the cavities are very Lorentz detuning sensitive or dark currents are generating the jitter in the higher gradient cavities – this really needs to be understood as it has major implications for XFEL and ILC.

# 1<sup>st</sup> Input Forward Flat

FB Off / AFF Off / No Beam

Normalized to the same average amplitude!

ACC4

ACC5

ACC6

The cause of the slight difference of the forward flat top shape for different cavities is that the forward input signal as detected is the sum of forward signal plus the reflected signal times F-R isolation. The isolation may be as low as 20dB on some channels (Stefan Simrock, DESY). HLRF requirements for power coupler isolation need to be discussed. Maybe 35dB is realistic starting point.

# Some Conclusions

---

- From the non-integral power spectrum, we can see there is clearly something going on at 10-15 frequency units (ACC4-2, 3, 6, 8) and at ~40 frequency units (ACC4-5, ACC5-2, 5, 6, 8, ACC6-1). The effect of ~40 frequency units seems bigger than that of ~10-15 units (one particular example is the effect of ~40 frequency units on ACC6-1). However, the contribution of them to the total integral power spectrum is relatively small, only about ~10-30%.
- The enormous signal on the spectrum for ACC6-1 would be consistent with the information that this cavity is unstable (Valeri Ayvazyan).
- Big amplitude deviation usually comes with large gradient tilt along the RF pulse flat top. The deviation of the flat top end is usually bigger than that of the start.
